Abstract

The placement of implants in a prosthetically driven position depends on the quantity and quality of available bone especially in the anterior region of maxilla. Implant placement and its restoration becomes clinically challenging when the alveolar ridge lacks sufficient bone volume. Additional surgical procedures are required to augment the bone deficiency in such clinical situations. Advanced procedures such as guided bone regeneration provides a conducive environment for successful placement of implants, where non-osseous cells are inhibited and osteoblast derived from the periosteum and the bones are induced to form new bone. This article presents a case report of simultaneous approach of guided bone regeneration and implant placement in the maxillary anterior with narrow ridge defect. After six months of healing period implant was aesthetically restored.

Introduction

Dental implants are considered as the first line of treatment in restoring missing teeth now days by most of patients and clinicians. The high predictability and success of osseointegration have led to a shift in the focus towards achieving ideal long-term esthetics with peri-implant bone and tissue architecture. Because prosthetically-driven implant placement is only possible when there is an adequate amount of bone, the presence of resorption can pose a significant clinical challenge. The extraction of teeth can result in up to 50% loss of alveolar ridge width within the first one to three years. This bone loss is exacerbated if the tooth is removed traumatically or if there are pre-existing endodontic or periodontal pathologies [1,2]. This often requires bone augmentation to create ideal gingival contours and esthetics. A variety of techniques and materials have been used to restore the necessary volume of bony tissue for supporting dental implants. The most commonly described methods in the dental literature are: Guided Bone Regeneration (GBR), onlay veneer grafting, inter-positional inlay grafting, ridge splitting technique and distraction osteogenesis [3-5].

Guided bone regeneration is a frequently used procedure for hard tissue reconstruction. The treatment concept advocates that regeneration of osseous defects is predictably attainable via the application of occlusive membranes, which mechanically exclude non-osteogenic cell populations from the surrounding soft tissues, thereby allowing osteogenic cell populations originating from the parent bone to inhabit the osseous wound. The studies suggest that bone regeneration is significantly enhanced when the invasion of soft tissue into osseous defects is mechanically impeded. There are two approaches in Guided bone regeneration (GBR) - simultaneous and staged approach. In simultaneous approach fixture placement and GBR are performed simultaneously and is indicated only in narrow ridge defects. In staged approach GBR is used to increase the alveolar ridge before fixture placement. This case report presents a simultaneous

approach of guided bone regeneration and implant placement in the maxillary anterior with narrow ridge defect [6-9].

Case report

A thirty five years old female patient reported with a chief complaint of missing anterior teeth and need for aesthetic restoration of the same with fixed prosthesis. She was wearing maxillary anterior removable partial denture from last 10 months. The patient gave the history of extraction due to mobility of upper anterior teeth one year back. Her medical history was non-contributory. Her expectations were reasonable and her psychological profile was good. On transgingival probing the presence of Seibert class II ridge in relation to maxillary anterior 11 was evident. There was a slight buccal defect in the gingiva in the region of tooth #11 due to normal shrinkage, probably exacerbated by pressure exerted from the removable appliance (Figure 1). The periapical radiograph revealed adequate bone height and mesio-distal bone width. It was explained to the patient that although implants represented an ideal treatment option, it would be necessary to simultaneously augment the bone to allow for optimal bone integration and stability of the implants. The patient agreed to the proposed surgical and prosthetic treatment plan.

A buccal full thickness mucoperiosteal flap was elevated following mid-crestal and intracrevicular incisions on the adjacent teeth. The

dimension of the ridge was deficient measuring 4.1 mm in width in the maxillary incisor region. A narrow platform implant (3.5 mm x 11.5mm; Nobel Replace Select Tapered) was placed epicrestally with an initial torque of 35N. The primary stability was good but in the mid-labial surface of 11 region three threads of the implant was exposed due to deficient ridge (Figure 2). This defect was treated with simultaneous guided bone regeneration using particulate bone graft alloplast (Bio-oss; Osteohealth Company, NY, USA) [10]. The grafted site was secured with a resorbable membrane (Healiguide, Encoll, Fermont, CA, USA) and tacks (Figures 3 and 4). Undermining of the periosteum to facilitate primary closure with tension free approximation of the flap was completed prior to suturing with 3-0 black silk suture (Ethicon, Johnson & Johnson Ltd. Aurangabad, India). Patient was advised to clean the surgical area with cotton dipped in 0.2% chlorhexidine mouth wash twice a day. Patient was called after one week for suture removal. Six months post operatively the maxillary second stage surgery was performed. This period was considered necessary for predictable osseointegration as the site was grafted. The implant head was exposed using a crestal incision and healing abutment was placed. 2 weeks post operatively a well formed gingival cuff was evident (Figure 5). The implant analog was placed and the impression was taken with rubber base impression material. The implant analog was transferred to the impression and the working model was made. Desired modifications were done in the esthetic abutment to achieve good emergence profile (Figure 6), upon which ceramic crown was prepared. The abutment was placed followed by cementation of ceramic crown in the patient's mouth (Figure 7). The patient was given proper supportive periodontal therapy and recalled every three months for one year to evaluate the periodontal status (Figure 8).

Discussion

Guided Bone Regeneration (GBR) is a technique in which bone growth is enhanced by maintaining the space and preventing soft tissue growth into the area utilizing either a resorbable or non-resorbable barrier membrane and achieving the bone regeneration. It may be performed in conjunction with the placement of the implant or during a surgical intervention prior to implant placement. Various different membrane materials have been used in experimental and clinical studies in the context of GBR treatment. However, before choosing the membrane type, some prerequisites are essential. These include: (1) Biocompatibility, *i.e.*, no interaction between material and tissue, (2) Cell occlusion properties, *i.e.*, to prevent fibrous connective tissue invasion, (3) Integration by the host tissues, (4) Clinical manageability and space making ability [11-13].

Non-resorbable membranes do not undergo the enzymatic degradation when placed in the living body as in the case of the resorbable membranes. Hence, they require a second surgical intervention in order to be removed. Moreover, the exposure of these

membranes may lead to total failure of the regeneration process. These disadvantages led to the development of resorbable membrane devices. Absorbable collagen membranes are more frequently in dentistry for guided bone regeneration (GBR). The great advantage of using absorbable membranes is that a second procedure to remove the membrane is not necessary. The membrane is made with a unique manufacturing process which creates a longer resorption profile suited to GBR procedures (six months). The material consists of a fibrillar matrix structure to provide strength for tacking or suturing the membrane if desired. This composition provides excellent handling characteristics when hydrated—thus improving adaptability to various defects [14-16].

This clinical report presentation illustrates restoration of a maxillary anterior partially edentulous ridge with dental implant. Due to the lack of sufficient bone volume to place implant, simultaneous guided bone regeneration was necessary. The defect area was grafted with freeze-dried bone grafts (FDBG) and covered with a Healiguide

barrier membrane, which was chosen in this case due to its excellent handling characteristics and a longer resorption profile (six months). It protected the graft material during regeneration. Excellent ridge width and soft tissue dimension was obtained, which provided for implant placement and restoration in the aesthetic zone with optimal results. A two-stage surgical procedure was performed with implant exposure after six months of implant placement and regeneration.

Conclusion

To maximize functional and esthetic results, implants should be placed accordingly to prosthetic needs and design. Due to bone resorption after extraction, ideal placement of implants would be often impossible without prior hard and soft tissue augmentation. Several techniques such as Guided Bone Regeneration (GBR), onlay veneer grafting, inter-positional inlay grafting, ridge splitting technique and distraction osteogenesis are available nowadays. Based on advantages and disadvantages of these techniques, solution of each case requires customization and often combination of these techniques. Thus a deep knowledge of these techniques will allow the surgeon to properly select the right combination for prosthetic needs and especially for the esthetic and function of patients.
