Abstract

Background: GI (glycemic index) is used to show the potency of foods to increase blood glucose. No research has been carried out about gender differences of GI of foods of distinct structures such as glucose and sucrose. We wanted to know if there is a big difference in GI depending upon sex to take foods.

Methods: We gave 50 gm of either glucose or sucrose in a cross over study to two groups of healthy men (n=36, mean age=20.6 ± 1.6) and women (n=35, mean age: 21.2 ± 0.7).

Results: There are no statistical differences in GI of glucose and sucrose in young men. Although glucose administration did not result in different glucose levels between men and women, sucrose administration caused lower glucose levels in women compared with men. Since AUC (area under the curve) of insulin of women who took sucrose was not necessarily high, women may have higher sensitivity to insulin upon the administration of sucrose. In fact, basic levels of blood glucose of all women were lower than basic blood glucose levels of men. HDL cholesterol levels were higher in women than men but LDL cholesterol levels were higher in men.

Conclusion: GI of sucrose was not significantly lower than GI of glucose in men. In women GI of sucrose was 66% of glucose. These results suggest that GI of substances of distinct structures such as glucose and sucrose was different between men and women. Young men seem to have more LDL, but less HDL-cholesterol compared with women, suggesting that men may be more atherosclerogenic from young age.

Introduction

Dietary carbohydrate clearly influences plasma glucose levels, but dietary fat and protein can also influence plasma glucose levels [1,2]. The total carbohydrate intake from a meal is a good indicator of postprandial plasma glucose [3-7], but gender and age differences have not been examined yet. Term of glycemic index (GI) has been introduced by Jenkins and coworkers in 1981 [7,8] and is defined as the area under the blood glucose curve measured two hours after consuming 50 g of test carbohydrates in relation to 50 g of glucose [9,10]. In 1997 [8,9], the term glycemic load (GL) was introduced to quantify the overall glycemic effect of food as to its specific carbohydrate content.

GL equals GI multiplied by the carbohydrate density of the food which is usually given as g carbohydrate per 100 g serving. Research on GI indicates that even when foods contain the same amount of carbohydrate, there are up to fivefold differences in glycemic impact [8-10]. In addition, several studies have found that the overall GI and glycemic load (GI × g carbohydrate) of the diet, but not total carbohydrate content, are independently related to the risk of developing type 2 diabetes [8,9], cardiovascular disease [11], and some cancers [12,13].

There were many reports about gender differences of glycemic index, glycemic loads and their relationship to mortality risks [14-20]. We recently reported [8] that there were big age differences in glycemic index when glucose or sucrose were given to young and aged men. When the amounts of blood glucose and insulin after the administration of glucose or sucrose were measured, glucose increased more despite increase in insulin old men in young men, nearly same amounts of insulin caused smaller increase in blood glucose levels. These results seem to indicated that glycemic index (GI) is very much different between old and young men even if the same foods with distinct structures are given, and insulin release to increase in glucose in young men is more sensitive than old men. There seems to be gender and age difference in foods uptakes, plasma levels of carbohydrates, lipids, and amino acids.

In this paper, we report differences in various foods uptakes, glycemic index, plasma levels of carbohydrates, lipids, and amino acids in young Japanese men and women.

Methods

Male and female college students were requested to participate in the experiments. We carefully assessed their health and allowed those who do not smoke, with no sign of health problems such as diabetes and hypertension, as well as no history of serious disease, to participate.

Ishii Y (2016) Gender differences in foods uptakes, glycemic index, BMI, and various plasma parameters between young men and women in Japan

Measurements of blood variables: After fasting overnight, participants were randomly assigned to groups. Depending on their group, each participant received a 500 mL solution containing 50 g of glucose or sucrose (or 500 mL water as a control). Either 50 g of glucose or sucrose was added and dissolved in each bottle containing 500 mL of water.

Participants were requested not to eat anything after 09:00 PM on the previous night and not eat anything for breakfast the following morning. Between 9:00 AM and 10:00 AM, blood was sampled using a syringe, and participants were given either glucose or sucrose solution or water as a control. We measured blood glucose using a finger stick (TERUMO kit) before and 120 min after the administration of glucose or sucrose. Furthermore, other plasma factors were measured after plasma was separated from blood. Ethylene diamine tetra acetic acid (EDTA) was used as an anticoagulant. Insulin was measured by the CLEIA (chemiluminescent immunoassay) method.

Lipid and lipoprotein concentrations (total cholesterol, HDL, TG) were determined using a Polychem Chemistry Analyzer (Polymedco Inc.). FFA concentrations were measured by a gas chromatography.

Ethics: This work was approved by the ethical committees of Showa Women’s University (15-02) and the NPO “International projects on food and health” (15-01) and was conducted in accordance with The Code of Ethics of the World Medical Association (Declaration of Helsinki) for experiments.

Statistics: The results are presented as means ±SEM. Statistical significance of the differences between groups was calculated according by one-way ANOVA. When ANOVA indicated a significant difference (P<0.05), the mean values of the treatment were compared using Tukey’s least significant difference test at P<0.05.

Results

Table 1 shows basic parameters of BMI, food uptakes, glucose and insulin levels and plasma levels of various lipids. Generally young men take more energy and various foods. Basic levels of blood glucose levels are lower in women than men. Plasma levels of LDL-cholesterol and TG are higher in men, but plasma levels of HDL-cholesterol are higher in women. Young men take more lipids from foods, but higher levels of LDL-cholesterol and lower levels of HDL-cholesterol may not be due to higher uptakes of lipids alone because there were no differences in TG levels between men and women.

Table 2 shows changes in lipids levels after the administration of glucose or sucrose. Generally young women took glucose or sucrose. There are no statistical differences glucose and sucrose in women. Sucrose administration resulted in lower levels of blood glucose (67%) compared to glucose administration.

Figure 3 shows that changes in blood glucose levels in young men or women after the administration of glucose. Although there was no statistical significance, blood glucose levels of young women tended to be lower than glucose levels of men.

Figure 4 shows that changes in blood glucose levels in young men or women after the administration of sucrose. Blood glucose levels were statistically significantly lower in young women compared with men.

Figure 5 shows AUC of insulin levels of men and women who took glucose or sucrose. There are no statistical differences glucose and sucrose levels after the administration of glucose and sucrose in men and women.

Discussion

There are many trials as to what kind of diets are healthier in terms

of decrease in body weight and mortality.

We recently reported [8] that there were big age differences in glycemic index when glucose or sucrose were given to young and aged men.

To study effects of various dietary prescriptions on body weight or mortality, we must know gender differences in foods uptakes and plasma factors such as glucose, insulin levels, or lipids levels in healthy people.
Oba et al. [19] reported the relationship among dietary glycemic index, glycemic load and carbohydrate uptakes and the risk of mortality from strokes and indicated that the hazard ratios increased in high dietary GI in women. On the other hand, Fan et al. [20] reported that gender significantly modified the effects of glycemic index and glycemic load on cardiovascular risk, and high glycemic load level was associated with higher risk of cardiovascular disease in women, but not in men. It has been recognized that diet plays a major role in increasing the risks of cardiovascular diseases. Dietary GI and dietary GL are used to evaluate the glycemic properties of the diet. The dietary GI was shown by Nurses Health Study to be associated with the risk of cardiovascular disease [21] and later with hemorrhagic stroke [22] and these associations were shown to be the most evident in overweight women in both studies. Later, similar findings for CVD risk have been reported in several, but not all studies [23-25].

These controversial results may have been obtained because basic studies of age or gender differences were not well performed. For example, GI of sucrose is theoretically 50% of glucose for all the populations. But our results [8] indicated that GI in response to sucrose was 82% compared with that of glucose in young men and 73.6% in older men.

In the present research, we showed that GI of sucrose in young men was not significantly different from GI of glucose in men, but GI of sucrose in young women was 67.8% of GI of glucose. We used substances of distinct structures such as glucose or sucrose which has 50% of glucose in the structure. Even substances of such distinct structure were used GI was different depending upon age and gender of persons who took such substances.

We should study more precisely roles of sex and ages in the determinations of GI. In Japan, there are larger numbers of type 2 diabetes mellitus (T2DM) patients in men than women. National Survey of Health and Nutrition 2015 in Japan indicated that the number of T2DM patients are 15.5% in men and 9.8% in women [25]. Probably higher sensitivity to insulin upon sucrose and sweet beverage as shown in the present research may be one of the reasons.
